 Rats

ABSTRACT

Purpose: This study compared different energy densities of laser on second degrees burns in rats aiming to determine the most effective dosimetry in stimulation of the healing process. **Methods:** Burns were induced in the dorsal skin of 54 animals divided into three groups (n: 18): 1-without treatment; 2-irradiated lesions by the Indium Gallium Phosphide (InGaP) 670nm (4.93J/cm²) laser; 3-irradiated lesions by the InGaP-670nm (9.86J/cm²) laser. Samples were collected on the 2, 10 and 18 days after injury for structural, morphometry, biochemical analysis and Western blotting.

Results: The energy densities examined were effective in significantly increasing the total number of fibroblasts and blood vessels and reduce the number of inflammatory cells particularly in irradiated lesions with 9.86J/cm². This same energy density significantly increased the amount of GAGs (Glycosaminoglycans), decreased the TGF-β1 (Transforming Growth Factor β1) and increased the VEGF (Vascular and Endothelial Growth Factor) during the experimental period. This energy density also significantly increased the Collagen type I and decreased Collagen type III and the active isoform of metalloproteinase 9 (MMP-9).

Conclusions: The energy density of 9.86J/cm² was more effective in promoting cellular responses related to neoangiogenesis, decreasing inflammation and collagen fibers reorganization.

1. Introduction

Burns produce large local and systemic physiological damage [1] such as the destruction of vascular and capillary integrity, edema formation [2]. The severity of a burn depends on the thermal agent and the contact time with the tissue and it can be evaluated according its depth in the Boyer's rating [3]. Burns result in functional limitations such as decreased body and environment control, as well as aesthetic problems that promote decreased self-esteem, social avoidance, and anxiety about the future [4]. The focus of therapy for burn patients has been of physical and social functionalities [5].

Tissue repair is a process characterized by interrelated events, into sequential phases: inflammatory, proliferative and remodeling under the action of specific cells, cytokines and various growth factors [6]. The TGF- β 1 (Transforming Growth Factor), especially released in the early stages of this process, is secreted by keratinocytes, fibroblasts and platelets, acting as chemotactic for neutrophils and monocytes at the wound site [7,8]. Another important growth factor in tissue repair is VEGF (Vascular and Endothelial Growth Factor) whose secretion is induced by hypoxia and low pH, conditions that stimulate angiogenesis [9]. Metalloproteinases are also involved in the modulation of tissue integrity and modulate the half-life of the molecules of ECM (Extracellular Matrix) by means of selective degradation [10]. GAG (Glycosaminoglycan) and (PGs) Proteoglycans; on the other hand, are involved in proliferation, migration and cell differentiation during tissue repair [11].

The LLLT (low-level laser therapy) is involved in the healing process triggering the photoactivation of cellular mechanisms. Chromophore located in the mitochondria seem to absorb the laser's red and infrared light triggering increased protein synthesis, ATP production, cell proliferation, and reorganization of collagen [12]. The LLLT has stood out among the many therapeutic methods [6,13–15] and has demonstrated in various studies that improves tissue repair as it promotes collagen synthesis and deposition, increased vascularity, inflammation reduction, accelerating the wound remodeling. In this way, it is a promising work tool in the burn wounds therapy [1,8,15–20]. However, its effects are dependent on the different irradiation parameters used such as energy density, wavelength, laser irradiation frequency and duration of treatment [21].

The wavelength of the laser is critical in its absorption by the tissues and their produced physiological effects. Among the therapeutic lasers also known as low-intensity lasers are Helium-Neon (He-Ne), Gallium Arsenide (AsGa), Aluminum-Gallium-Indium-Phosphorus (AlGaInP) and Arsenide-Gallium-Aluminum (AsGaAl). The wavelengths between 632.8 and 904nm are widely used in tissue repair [2,15,22]. Two different types of laser (670-InGaP and 830-nm GaAlAs) are used for Chiarotto et al. [8] in the treatment of second-degree burns in rats and it was observed that the laser 670-nm InGaP was more effective in increasing the numbers fibroblast at the injury site. Other authors have also demonstrated the beneficial effects of low intensity laser in tissue repair using 670nm [6,23,24].

Thus, this study compared the action of different energy densities of Indium Gallium Phosphide (InGaP) 670nm laser in

second degree burns repair in Wistar rats to identify the best dosimetry to be used in treating this type of injury.

2. Methods

2.1. Animal model

The experimental procedure was developed using 54 male Wistar rats obtained from Hermínio Ometto University Center (UNIARARAS) — Center of Animal Experimentation. These animals with 120 days with ± 300 g were maintained in individual cages under a 12/12-h light/dark cycle at a constant temperature ($23 \pm 2^\circ\text{C}$) and humidity (55%).

2.2. Experimental procedure

In dorsal skin of all animals the burn lesions were induced according the protocol developed by Chiarotto et al. [8]. These were divided into three groups of 18 animals: group 1, untreated; group 2, lesions irradiated with an InGaP laser at 670nm, $4,93\text{J}/\text{cm}^2$; group 3, lesions irradiated with an InGaP laser at 670nm, $9,86\text{J}/\text{cm}^2$. Through anesthetic overdose and cervical dislocation, six animals per group were euthanized in two, ten and eighteen days after experimental injuries for collection of tissue samples and analysis morphometric analysis ($n=3$), Western blotting, quantitative analysis of glycosaminoglycans, hydroxyproline and zymography to metalloproteinases ($n=3$). The surgical and experimental procedures received approval by Ethics Committee of the Hermínio Ometto University Center (UNIARARAS) (protocol no. 022/2013) and conducted according with the Guide for the Care and Use of Laboratory Animals [25]. The animals were healthy and procedure did not promote stress.

2.3. Laser irradiation

The treatments occurred daily for 18 days according to protocol Chiarotto et al. [8]. For laser therapy was used a Physiolum Dual Bioset[®] InGaP laser (Indústria de Tecnologia Eletrônica Ltda., Rio Claro, São Paulo, Brazil) at a wavelength of 670nm (visible red), selected in the continuous mode, with an output power of 30mW, with the beam covering an area of $0,073\text{cm}^2$, applied for 12s, energy density of $4,93\text{J}/\text{cm}^2$ (energy per point of 0.09J, total energy of 0,36J); and for 24s, energy density of $9,86\text{J}/\text{cm}^2$ (energy per point of 0.18J, total energy of 0,72J). The utilization of two energy densities was based on studies performed by Ezzati et al. [16,17], Novaes et al. [26] and Fiório et al. [27] and the different doses and wavelength used in this protocol were chosen according to previous studies used by our research group in burns [6,14,24]. For irradiation the apparatus calibration was performed by the manufacturer.

2.4. Structural and morphometric analysis

The sample collection (25mm in diameter) was made following different phases of tissue repair in skin.

After removing, the fragments of tissue were immediately fixed in 10% formaldehyde in Millonig buffer, pH 7.4, for 24h at room temperature. After that, they were washed in buffer

and submitted to routine procedures for embedding in Paraplast™ (Histosec®, Merck). The blocks were cut into 6- μm longitudinal sections and stained with Masson's trichrome for collagen fibers quantification in the repaired area (% area); toluidine blue in McIlvaine buffer (pH 4.0), for histomorphometric analysis of the epidermis and dermis and evaluation of the number of blood vessels and fibroblasts, with Dominici stain for intracellular granules detection in the polymorphonuclear leukocytes [28]. The numbers of newly formed blood vessels, fibroblasts and polymorphonuclear leukocytes ($n/10^4 \mu\text{m}^2$) in the repaired area were determined in longitudinal sections stained [28]. Three samples of $10^4 \mu\text{m}^2$ were made for each of the five sections of each animal per group. The documentation of sections were made on days 2, 10 and 18 of treatment and each sample were captured and digitized in bright field with a Leica DM2000 photomicroscope. For morphometric analysis, samples were examined using the virtual Leica Image Measure™ grid and Sigma Scan Pro 6.0™ programs [29].

2.5. Biochemical analysis and Western blotting

The densitometry values of TGF β 1, VEGF, Collagen type I and type III signals were developed according to a protocol developed by Jácomo et al. [24] and expressed relative to proteins stained with Ponceau S, which were taken as 100% [30]. The results were analyzed by ANOVA and the Tukey post-test ($p < 0.05$) using the GraphPad Prism® 3.0 program.

2.6. Quantitative analysis of glycosaminoglycans (GAGs)

The glycosaminoglycans extraction of tissue fragments was made according to the DMMB method [31]. The reading was made in visible spectrophotometer light at 526nm.

2.7. Quantification of hydroxyproline (Pro-OH)

Fragments were weighed, immersed in acetone for 48h and then in chloroform: ethanol (2:1) for 48h. The samples were hydrolyzed in 6N HCl (1mL for each 10mg of tissue) for 16h at 110°C, and neutralized with 6N NaOH. For the quantification of total collagen, samples were treated with chloramine T solution, according to Stegemann and Stalder [32] with some modifications. For the standard curve, HO-Pro concentrations were between 0.2 to 6mg/mL using absorbance at 550nm in a Spectrophotometer.

2.8. Molecules extraction from extracellular matrix

The tissue samples were fractionated with the help of a scalpel blade and fragmented in Polytron® soaked in saline. After a quick centrifugation, the precipitate was treated with 15 volumes of 50mM sodium acetate buffer pH 5.8 containing Gu-HCl 4M, EDTA 50mM and PMSF 1mM. The extractions were processed under constant agitation at 4°C for 24h. After the extraction period, the samples were centrifuged at 18,000rpm for 20min at 4°C in Beckman centrifuge J2-21 (ROTOR JA-20). After centrifugation, the supernatant (total extract) was used for zymography [33].

2.9. Zymography to metalloproteinases

The supernatant from each sample (50 μg protein) was used of according protocol of Silva et al. [34] for the analysis of MMP-9 activity.

2.10. Statistical analysis

The results of the morphometric analysis, Western blotting and quantitative of Hydroxyproline and GAGs were reported by mean and standard deviation ($X \pm SD$) and the values were compared by ANOVA and Tukey's post hoc test ($p < 0.05$) using software version

3. Results

3.1. Morphometric analysis

The number of polymorphonuclear leukocytes in the area of the lesion progressively decreased throughout all the study period when observed the different experimental groups, but in the samples of lesions irradiated with 9.86J/cm² it was observed a significant reduction of these cells in the 18th experimental day relative to the control and to the 4.93J/cm² (Table 1) irradiated lesions.

The quantification of the newly formed vessels increased in the irradiated lesions on the 10th day. But on the 18th day there was an increase only in the 9.86J/cm² (Table 1) irradiated lesions.

Morphometric analysis done on samples taken at the site of injury showed an increase in the total number of fibroblasts in injuries irradiated with 4.93J/cm² and 9.86J/cm² on the 10th and 18th days compared to those that received no treatment (Table 1). No differences were found when comparing the obtained data from the irradiated lesions between the different doses of energy.

3.2. Quantification of hydroxyproline and glycosaminoglycans

In the quantification of GAGs was observed increase on the 18th day experimental in samples from lesions irradiated with energy density of 9.86J/cm² and the hydroxyproline content showed no significant differences between groups throughout all experimental periods (Table 2).

3.3. Western blotting

The TGF- β 1 expression demonstrated through the densitometry revealed that the lesions irradiated with different used energy densities, showed gradual reduction of this growth factor in the different experimental periods compared to the control (Fig. 1). Treatment with the energy density of 9.86J/cm² was significant in this parameter when the data were compared with the energy density of 4.93J/cm² (Fig. 1).

Densitometric analysis of VEGF expression showed an increase of this protein in the lesions irradiated with energy density of 9.86J/cm² throughout the experimental period especially on the 10th day (Fig. 1).

Table 1 – Morphometric parameters evaluated in the repair area of second-degree burns in rats in different treatment groups and experimental periods.

1, Animals not submitted to any treatment; group 2, lesions irradiated with an InGaP laser at 670nm, 4.93J/cm²; group 3, lesions irradiated with an InGaP laser at 670nm, 9.86J/cm². Samples were collected from each group 2, 10 and 18 days after injury. Values are the mean and standard deviation of each group and were compared by ANOVA with Tukey's post hoc test (p<0.05). (*) significant difference.

As for Collagen, the analyzes of the data showed a decrease in the expression of type III and an increase on type I over the study period, especially in lesions irradiated with energy density of 9.86J/cm², compared to other groups (Fig. 1).

3.4. Zymography

Zymography for MMP-9 (Fig. 2) detected the latent and active isoform at all times and experimental groups, and were observed significantly higher values compared to the control in the irradiated lesions. However, a gradual decrease of the active isoform was observed from the 2nd to the 18th experimental day in the irradiated groups, with highlighted on the energy density of 9.86J/cm².

4. Discussion

The purpose of this study was to compare different energy densities during the repair process in its different phases: inflammation (2nd day), granulation tissue formation and reepithelialization (10th and 18th days). All phases of tissue repair process are affected positively with the LLLT and the

choice of wavelength and energy density are crucial to a successful treatment [35]. The energy per point also is important in the application of laser because it the time of tissue exposure and the output power improvement the study reproducibility [36]. Ezzati et al. [16] have compared two types of energy density (2.3–11.7J/cm²) in the treatment of second degree burns in mice and observed that the irradiation fluence of 11.7J/cm² significantly favored the repair of wounds. The application of different energy densities (3 and 30J/cm²) on excisional wounds in Wistar rats resulted in increased tissue cellularity, angiogenesis, collagen fibers and glycosaminoglycans synthesis, especially when using a density of 30J/cm² [26].

The quantitative analysis revealed in this study a decrease in the number of polymorphonuclear leukocytes, mainly present during the inflammatory phase (day 2), in samples of the irradiated burns particularly with 9.86J/cm² indicating that the choice of the energy density is necessary to the treatment success [35]. LLLT, as stated in many experimental investigations, has beneficial effects on the reduction of cells involved in the inflammatory infiltrate [6,14] Chiarotto et al. [8] compared two kinds of laser (670-nm InGaP– 4.93J/cm² and 830-nm GaAlAs– 4.48J/cm²) in the treatment of second degree burns and observed that both significantly reduced the

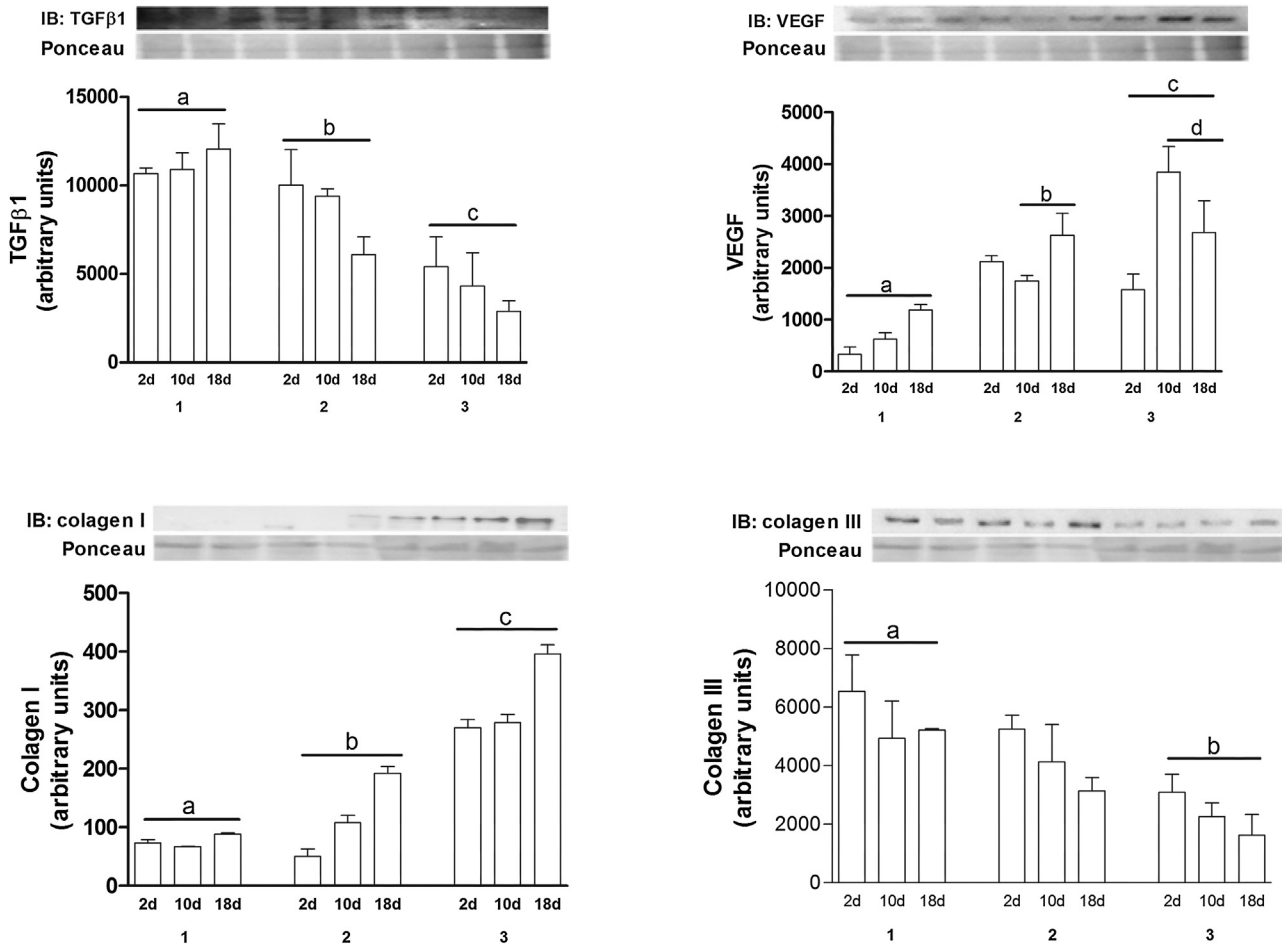

Fig. 1 – Immunoblotting (IB) of the protein expression of TGF-β1 (A), VEGF (B), Collagen type I (C) and type III (D) in the area of the burn in the dorsal skin of rats in the different experimental groups. 1, animals not submitted to any treatment; group 2, lesions irradiated with an InGaP laser at 670nm, 4.93J/cm²; group 3, lesions irradiated with an InGaP laser at 670nm, 9.86J/cm². Samples were collected from each group 2, 10 and 18 days after injury. Typical blots are shown above the average of densitometry. Data are presented as mean and standard deviation for each group. The values were compared using ANOVA with Tukey’s post hoc test (p < 0.05). The letters indicate significant differences for each graph: TGF-B1, Collagen type I: a vs. b and c vs. b; VEGF: a vs. b and c vs. d; Collagen type III: a vs. b.

number of polymorphonuclear leukocytes in the repair process. Silveira et al. [37] also observed a reduction in the area of excisional wounds comparing different wavelengths and irradiation doses (HeNe laser, 904nm and GaAs, 660nm and energy density of 1J/cm², 3J/cm² on both) and observed beneficial effects of both laser types used in different doses, since it induced collagen synthesis and reduced inflammatory phase.

The decreased TGF-β1 expression during the experimental period also aims to reduce the inflammatory process in the irradiated lesions, since the presence this protein is important in the early stages of the tissue repair process recruiting leukocytes in site of lesion inducing inflammation [7,38]. In this phase also occurs the important participation of some gelatinases like MMP-9, which is found in the granules of neutrophils and macrophages, and is often released at the site of the lesion [39]. Studies have observed that there is a dose-dependent relationship between expression of TGF-β1 and MMP-9 [40,41]. Hsieh et al. [42] showed that this growth factor

induces the expression of MMP-9, which probably explains the results found in our study where we observed gradual reduction of gelatinase expression and of TGF-β1, especially for samples submitted to treatment with energy density 9.86J/cm² demonstrating that this one was more effective in reducing the inflammatory process in the last stages of the trial period. The MMP-9 plays an important facilitating role in the events observed during the inflammatory process [43]. Reiss et al. [44] considered that the excessive and prolonged production of MMP-9 leads to a disturbance in wound repair, but if this metalloproteinase is inhibited to epithelialization is impaired which highlights its modulating role in the homeostasis of tissue repair.

Comparison of the irradiation of lesions with different energy densities showed that especially the energy density 9.86J/cm² caused an increase in newly formed vessels in the 10th and 18th experimental days (proliferative phase). Corazza et al. [45] compared the angiogenic effects of LLLT (5J/cm² and 20J/cm²) and the LED (Light-emitting diode)

Fig. 2 – (A) Zymogram for analyzing the isoforms latent (92kDa) and active (83kDa) of MMP-9 in the wound healing process of second-degree burns in rats diabetics in different treatment groups and experimental periods. (B) Densitometry of the bands (pixels) corresponding to the latent isoforms (92kDa) and active (83kDa) of MMP-9 in the wound healing process of second-degree burns in rats diabetics in different treatment groups and experimental periods (n=3/group/time). Group 1, animals not submitted to any treatment; group 2, lesions irradiated with an InGaP laser at 670nm, 4.93J/cm²; group 3, lesions irradiated with an InGaP laser at 670nm, 9.86J/cm². Samples were collected from each group 2, 10 and 18 days after injury. Values are the mean and standard deviation (x10³) of each group and were compared by ANOVA with Tukey's post hoc test (p < 0.05). (*) significant difference.

(5J/cm² and 20J/cm²) in the treatment of induced wounds in Wistar rats and they observed that the energy density of 5J/cm² was more effective in promoting formation of new vessels. Other authors have also shown that LLLT improves microcirculation and angiogenesis at the site of injury [6,8,14]. In our study, it was also observed an increase of VEGF expression in irradiated lesions compared to control in last experimental periods. However, radiated lesions with energy density of 9.86J/cm² showed an increase in the expression of this growth factor mainly on the 10th day indicating that this dose of energy was more effective in this parameter. The decrease on day 18th in the same dose of energy indicates the formation of new vessels since VEGF is also stimulated when the cells are subjected to hypoxia [46,47].

Quantitative analysis of samples irradiated in different energy density used in our study showed that both increased of fibroblasts in the last experimental periods studied. (proliferative phase) Chiarotto et al. [8] also observed it when used the laser 670nm InGaP, 4.93J/cm² in second degree burns. Silveira et al. [37] considered that the increase of collagen observed in irradiated excising lesions, especially in 3J/cm² in rats was a consequence of the acceleration of the processes of migration

and proliferation of fibroblasts induced by this treatment. Regarding collagen fibers our results indicate a growing reorganization of the same as it was a progressive decrease of Collagen type III and increase on Collagen type I in the irradiated injuries. In both it was detected a significant difference in the samples treated with energy density of 9.86J/cm². The evaluation of these two types of collagen have been an important indicator in the progression of the repair process and that in the early stages predominates the synthesis of Collagen type III which is gradually replaced by Collagen type I [48-50]. It is widely recognized that therapies that stimulate the synthesis of Collagen type I lead to increased collagen maturation and are used due course in wound care [51,52].

Regarding the concentration of hydroxyproline, an important indicator of synthesis and deposition of collagen fibers [53], the data analyzed showed increasing during the experimental period in the irradiated lesions compared to non-irradiated lesions, although these have not shown significant differences between the experimental groups.

The glycosaminoglycan content observed in our study demonstrated the significant influence of photobiostimulation energy density of 9.86J/cm². This result is relevant since the GAGs are involved in the development of an important functional and structural support migration and cell differentiation [54].

The results found in this study corroborate with the literature that indicates that low intensity laser therapy can be used in clinical practice. These lasers do not deliver enough power to damage tissue, but they do deliver enough energy to stimulate tissue repair [55]. It also contributed to add that the therapy with energy density 9.86J/cm² is effective in the treatment of second degree burns.

5. Conclusion

The different energy densities of InGaP-670nm laser studied promoted beneficial biomodulators effects on the repair burns in this experimental model, as promoted neoangiogenesis, decreased inflammation and reorganization of collagen fibers. The energy density of 9.86J/cm² was more effective in promoting cellular responses related to these parameters. Thus, burns being a worldwide public health problem, it is important that further investigation in the search of a dose, wavelength and treatment duration ideal in use of LLLT in the therapy of this type of lesions gets done.

Conflict of interest

We declare that no conflict of interest in this study.
